Filler-gap dependency comprehension at 15 months: The role of vocabulary

Laurel Perkins  and Jeffrey Lidz

University of Maryland

ABSTRACT

15-month-olds behave as if they comprehend filler-gap dependencies such as *wh*-questions and relative clauses. On one hypothesis, this success does not reflect adult-like representations but rather a “gap-driven” interpretation heuristic based on verb knowledge. Infants who know that *feed* is transitive may notice that a predicted direct object is missing in *Which monkey did the frog feed ___?* and then search the display for the animal that got fed. This gap-driven account predicts that 15-month-olds will perform accurately only if they know enough verbs to deploy this interpretation heuristic; therefore, performance should depend on vocabulary. We test this prediction in a preferential looking task and find corroborating evidence: Only 15-month-olds with higher vocabulary behave as if they comprehend *wh*-questions and relative clauses. This result reproduces the previous finding that 15-month-olds can identify the right answer for *wh*-questions and relative clauses under certain experimental contexts, and is moreover consistent with the gap-driven heuristic account for this behavior.

ARTICLE HISTORY

Received 9 March 2018
Accepted 20 August 2019

1. Introduction

Language acquisition, like learning in general, is incremental: What children can learn about their language depends on what they already know. The way learners experience their input changes over the course of development. Children rely on immature knowledge of their language to identify the structure and meaning of sentences they hear, and the limited portions of the input they can parse become the data they use to draw further inferences about their language. This raises a puzzle. If learners can veridically parse the input, then there is nothing to learn from it; but if they cannot veridically parse the input, then it is unclear how they avoid faulty inferences or even learn from it at all (Fodor 1998; Valian 1990). In this article, we examine how language learners perceive and learn from their input, given only partial knowledge of their language.

Our case study is the intersection of verb learning and filler-gap dependency acquisition. Learners draw inferences about verbs’ argument-taking properties from observing how they distribute in transitive and intransitive clauses (Fisher et al. 2010; Lidz, White & Baier 2017). But it is unclear how those observations of transitivity arise, given the surface variability of transitive and intransitive clauses both within and across languages. For example, recognizing the arguments of a clause may be straightforward for simple declarative sentences, like (1), but more difficult for complex clause types that do not follow the language’s canonical word order, like the filler-gap dependencies in (2):

- (1) a. John ate a sandwich.
b. John ate.
- (2) a. *What* did John eat ___ ?
b. I made *the sandwich* that John ate ___ .

A child familiar with the canonical subject-verb-object word order of English would recognize that sentences like (1a) are transitive, containing both subjects and objects, whereas sentences like (1b) are intransitive, containing only subjects. But recognizing the arguments of the *wh*-object questions and relative clauses in (2) may be more difficult. These sentences do not have direct objects after the verb, but they are underlyingly transitive. In both cases, an argument acting as the object of the verb (henceforth the “filler,” in italics) stands in a nonlocal relation to the position in which it is interpreted (henceforth the “gap,” marked by). To identify the structure of these sentences, a child must determine that they do not contain intransitive uses of *eat* but instead contain a particular type of nonlocal predicate-argument relation.

This article investigates the following question: When do children recognize clause transitivity in sentences containing filler-gap dependencies? Prior literature argues that infants begin to represent the full structure of *wh*-questions and relative clauses at the age of 20 months, although they behave as if they can comprehend these sentences as early as 15 months (Gagliardi, Mease & Lidz 2016; Seidl, Hollich & Jusczyk 2003). On this hypothesis, acquisition of filler-gap dependencies is driven by developing knowledge of verb argument structure. If a child can detect when a predicted argument of a transitive verb is unexpectedly missing, she may start searching the sentence for signals of the filler-gap dependency that is responsible. Thus, 15-month-olds’ apparent comprehension of these dependencies may not be due to adult-like representations but rather to a “gap-driven” interpretation heuristic based on their initial detection of predicted but missing arguments of verbs.

The gap-driven learning hypothesis predicts that 15-month-olds will only appear to understand *wh*-questions and relative clauses if they have learned enough verbs to deploy this interpretation heuristic. Therefore, performance should depend on vocabulary at this age. In the current study, we confirm this prediction: Using total productive vocabulary as a proxy for verb knowledge, we find that only high-vocabulary 15-month-olds appear to comprehend filler-gap dependencies. We discuss possible explanations for this correlation with vocabulary and argue that our findings are consistent with the gap-driven hypothesis, although alternative accounts remain to be tested given the indirect nature of this evidence. When considered together with prior literature, these results contribute another piece of evidence suggesting a connection between verb argument structure and clause structure acquisition in early syntactic development.

2. Background

Filler-gap dependencies are one of the most common types of complex clauses in child-directed speech. English-learning children hear a large number of *wh*-questions even before their second birthday (around 15% of their total input), the majority of which contain noncanonical word orders (Newport, Gleitman & Gleitman 1977; Stromswold 1995). Relative clauses are rarer in child-directed speech and are on the surface quite different from *wh*-questions but nonetheless share similar underlying structural properties (Chomsky 1977). Both cases involve a dependency between a displaced argument and the thematic position where the argument is interpreted. The length of this dependency can be relatively short, as in (2), or can hold across arbitrarily long distances, as in (3). Furthermore, neither type of filler-gap dependency can cross certain structures that are “islands” for dependency formation (4) (Chomsky 1977; Ross 1967).

- (3) a. *What* did Jake believe that Susan claimed that John ate ?
 b. I made *the sandwich* that Jake believed that Susan claimed that John ate .
- (4) a. **What* did Jake believe Susan’s claim that John ate ?
 b. *I made *the sandwich* that Jake believed Susan’s claim that John ate .

Unlike in English, in some languages *wh*-questions do not on the surface appear to involve filler-gap dependencies. In “*wh*-in-situ” languages like Chinese, Japanese, and Korean, *wh*-phrases are pronounced in their thematic position:¹

- (5) *Hufei mai-le shenme* (Mandarin Chinese; Cheng 2003)
 Hufei buy-PERF what^c
 What did Hufei buy?

Given the variety of forms that filler-gap dependencies can take, there are several problems that children must solve to be able to recognize them in their input. Children need to learn whether they are implicated in constructions like *wh*-questions and relative clauses, and which surface forms in their language signal that they are present. In English, surface signals for filler-gap dependencies include *wh*-words (e.g., *what*), subject-auxiliary inversion, do-support, and relativizers (e.g., *that*). Adult speakers make use of these signals efficiently in sentence processing to identify fillers and predict upcoming gaps (“filler-driven” parsing) (Aoshima, Phillips & Weinberg 2004; Crain & Fodor 1985; Frazier & Clifton 1989; Frazier & d’Arcais 1989; Sussman & Sedivy 2003; Traxler & Pickering 1996). But because these signals are language-specific, children must learn them. And to arrive at the correct interpretation of filler-gap dependencies, children furthermore must identify the particular relation that holds between the displaced argument and a nonlocal predicate—to identify the thematic position where the filler should be interpreted. This is not a trivial task, as gaps are phonologically null in languages like English.

2.1. Hypothesis: Gap-driven learning

In one proposal, children begin to identify filler-gap dependencies by detecting when a phrase stands in relation to a verb that is locally missing a predicted argument (Gagliardi, Mease & Lidz 2016). In other words, although mature parsing of these dependencies is filler-driven, the acquisition of these dependencies may be gap-driven. For example, learners might use the knowledge that some verbs cannot freely alternate between transitive and intransitive frames:

- (6) a. Amy fixed her bicycle.
 b. *Amy fixed.

A child who knows that *fix* requires a direct object might detect that it is missing after the verb in a *wh*-object question:

- (7) *What* did Amy fix ___ ?

She may then be driven to examine the sentence for cues to what happened to this unexpectedly missing argument and thus start learning the signals of the filler-gap dependency that is responsible: for example, that *what* is an argument *wh*-word and that do-support can occur in *wh*-object questions. The detection of a direct object gap will also allow the child to correctly interpret this particular filler-gap dependency, interpreting *what* as questioning some unknown patient of fixing by relating it to the empty position where *fix* would assign that thematic role.

The gap-driven learning hypothesis proposes a tight relationship between filler-gap dependency and verb argument structure acquisition. Learners need to know which verbs require direct objects in order

¹On many accounts, *wh*-phrases in these languages still take scope in a higher clausal position by undergoing covert displacement that happens to be inaudible (Aoun, Hornstein & Sportiche 1981; Huang 1982). Some have also argued for nonmovement accounts of *wh*-in-situ, such as binding by a covert operator (Reinhart 1998), or for different *wh*-in-situ representations across different languages (Cole & Hermon 1994). See Cheng (2003) for an overview.

to notice when those arguments are needed and missing. In other words, learners need to detect that sentences like (7) contain direct object gaps, rather than intransitive uses of verbs—but in order to do so, they must know which verbs are transitive. This account therefore posits that learners use verb transitivity knowledge to drive filler-gap dependency acquisition, rather than the other way around.

This proposal stands in contrast to another logical alternative: that filler-gap dependency acquisition is actually filler-driven. Under this alternative, the first step for the learner is to use distributional evidence to cluster the *wh*-words in her language into an equivalence class, by tracking function words that appear clause-initially in questions. The second step is to label this cluster as the set of *wh*-words in her language, by identifying that these words stand in particular nonlocal relationships with a predicate. Having done so, the learner might then use the presence of a *wh*-word to facilitate verb argument structure acquisition: An argument *wh*-word signals an upcoming argument gap and enables the learner to differentiate direct object gaps from intransitive uses of verbs. The filler-driven hypothesis therefore posits that verb transitivity acquisition occurs after learners identify at least some of the filler-gap dependencies in their language.

The first step of this alternative may be feasible. Indeed, Mintz, Newport & Bever (2002) found that an algorithm that clustered words only based on their immediately preceding and following sentence environments in child-directed speech was able to cluster the set of English *wh*-words when tested on the Nina corpus (Suppes 1974), although it did not appear to identify such a cluster for the Peter corpus (Bloom 1970) in CHILDES (MacWhinney 2000).² However, it is less clear how the learner would proceed from identifying this cluster of words to identifying the particular nonlocal relationships that they participate in without using verb transitivity information. Because adjunct *wh*-words (like *when* and *where*) do not predict upcoming argument gaps, a learner cannot use the mere presence of a *wh*-word to infer that a verb is being used in an argument-gap construction, rather than intransitively. Instead, the learner would need to rely on the semantics of particular *wh*-words to determine which of them are questioning unknown arguments of predicates, and which are questioning times, locations, manners, and reasons. This introduces a new puzzle, which is how a child identifies the semantics of these words—particularly, how a child determines which are the argument *wh*-words, without first knowing whether they stand in relation to an argument gap.

The gap-driven and filler-driven learning hypotheses make different empirical predictions. Under gap-driven learning, because filler-gap dependency acquisition depends on learning verb transitivity, it should come developmentally later. Under filler-driven learning, the reverse is true: Filler-gap dependency acquisition facilitates verb transitivity learning, so it should come at the same time or developmentally earlier.

2.2. Prior experimental results

Only two previous experiments have studied the comprehension of filler-gap dependencies prior to the age at which infants begin producing *wh*-questions in their own speech, around 20 months (Stromswold 1995). These studies have found a complex pattern of results.

In a preferential looking task, Seidl, Hollich & Jusczyk (2003) tested infants' comprehension of *wh*-questions at the ages of 13, 15, and 20 months. Infants saw videos of two objects interacting, such as a book bumping into a set of keys. They then saw both objects on different sides of the screen while hearing a subject (8a), object (8b), or *where wh*-question (8c):

- (8) a. *What* ___ hit the keys?
 b. *What* did the book hit ___ ?
 c. *Where* are the keys ___ ?

²Note that the goal of this computational model was not to identify closed-class categories like *wh*-words but rather to use closed-class items to help identify lexical categories like nouns and verbs.

The researchers found that only 20-month-old infants reliably looked at the target image for all three of these question types. Thirteen-month-olds showed no evidence of successful comprehension, and 15-month-olds were only partially successful: They performed above chance for subject and *where*-questions but not for object questions. The authors attribute this asymmetry in performance to difficulty either representing or processing the longer dependency between the filler and the gap in an object *wh*-question, as compared to a subject question. This explanation presupposes that 15-month-olds are aware that these sentences contain filler-gap dependencies and are attempting to process those dependencies online.

Gagliardi, Mease & Lidz (2016) note that there are several properties of Seidl, Hollich & Jusczyk's design that may have been particularly difficult for younger age groups. In particular, subject versus object questions were presented as a within-subjects variable with only two trials of each type; furthermore, because only one event of hitting was presented in a trial, there was no uncertainty about the agent or patient of hitting that would pragmatically license a *wh*-question. In their design, Gagliardi, Mease & Lidz presented infants with six trials in which an event occurred twice: for instance, a dog bumped a cat, who then bumped a different dog. At test, infants saw images of both dogs and heard either a subject or object *wh*-question or relative clause, with sentence type between subjects:

- (9) a. *Which dog* __ bumped the cat?
 b. *Which dog* did the cat bump __ ?
- (10) a. Show me *the dog* that __ bumped the cat.
 b. Show me *the dog* that the cat bumped __ .

The researchers found a different pattern of behavior than reported by Seidl, Hollich & Jusczyk. Fifteen-month-olds appeared to successfully comprehend both subject and object *wh*-questions and moreover did just as well for both subject and object relative clauses. In the second half of trials, they looked at the correct dog for all sentence types in (9–10) and showed no evidence of the subject-object asymmetry reported in Seidl, Hollich & Jusczyk, not even for the syntactically more complex relative clauses. Twenty-month-olds also succeeded on both types of *wh*-questions in the second half of trials and in this respect appeared similar to the 20-month-olds tested by Seidl, Hollich & Jusczyk. However, they performed surprisingly worse with relative clauses than their younger peers: They did not look above-chance at the right dog for either sentence in (10).

Gagliardi, Mease & Lidz argue that this unexpected decrease in performance over development is an example of U-shaped learning, in which a developmental change causes infants to perform temporarily worse on a task than they did when they were younger. In particular, they posit that infants at 15 and 20 months used different strategies for processing the sentences in their task. In their account, 15-month-olds' success is not due to an awareness of the filler-gap dependencies in these sentences, as Seidl, Hollich & Jusczyk assumed. Instead, 15-month-olds succeeded through an interpretation heuristic based on developing knowledge of argument structure: specifically, the ability to predict an argument in a particular position and notice when it is missing.

Independent evidence exists for developing argument structure knowledge around this age: For example, the 15-month-olds tested by Jin & Fisher (2014) were able to draw inferences about the meaning of a novel verb on the basis of hearing it in a transitive frame, and Lidz, White & Baier (2017) found that high-vocabulary 16-month-olds predicted an upcoming direct object for a known transitive verb during online sentence processing. In Gagliardi, Mease & Lidz's task, infants who had learned that *bump* is transitive, either by prior experience or because it was introduced in transitive clauses during familiarization, may have noticed that a predicted argument is missing in (9–10). They may then have inferred that the experimental task was to locate the referent of that missing argument by searching the display for the animal that got bumped. Identifying the answer would thus be possible without recognizing that an earlier phrase stands in relation to the verb—that the

filler (*which dog* or *the dog*) should be understood as that missing argument. This means that length of the filler-gap dependency would be irrelevant to their ability to respond appropriately in the task. By hypothesis, 15-month-olds had no difficulty responding to the longer filler-gap dependencies in object *wh*-questions or relative clauses because they were not attempting to process them as filler-gap dependencies at all. If this is the case, Seidl, Hollich & Jusczyk's finding that 15-month-olds had difficulty with object *wh*-questions may be better understood as difficulty with some aspects of their task design.

On Gagliardi, Mease & Lidz's hypothesis, 20-month-olds differ from 15-month-olds in their syntactic development. Twenty-month-olds may have identified that these sentences contain filler-gap dependencies and attempted to represent the filler as an argument of the verb but faced difficulty deploying their syntactic knowledge online to resolve those dependencies in relative clauses. Gagliardi, Mease & Lidz argue that this is because the cues for argument displacement are less apparent in relative clauses than in *wh*-questions. For example, relative clauses lack subject-auxiliary inversion and *do*-support, and the relativizer *that* is homophonous with other words in the language (such as demonstrative *that*). These weaker cues may make it challenging for learners to encode the filler or retrieve it in memory during online sentence processing, resulting in comprehension difficulty. This account predicts that 20-month-olds should improve on relative clauses if they contain stronger cues to displacement, and the researchers confirmed this prediction in a follow-up study that tested *wh*-relatives:

- (11) a. Show me *the dog* who ___ bumped the cat.
 b. Show me *the dog* who the cat bumped ___ .

Because the relativizer *who* is a *wh*-word, it more strongly signals the presence of the filler in these sentences, potentially facilitating online processing. Twenty-month-olds were able to identify the correct dog for these *wh*-relatives, indicating that processing difficulty may have indeed have been responsible for their earlier failure with *that*-relatives. Fifteen-month-olds, by hypothesis, faced no difficulty with *that*-relatives because they were not attempting to resolve any nonlocal dependency in these sentences.

If Gagliardi, Mease & Lidz's account of their findings is correct, these results point toward a developmental trajectory that is consistent with the gap-driven learning hypothesis. In this account, the ability to identify filler-gap dependencies emerges around the age of 20 months. Younger infants, such as the 15-month-olds in these studies, may be able to infer what the experimenter is talking about by using their argument structure knowledge—by detecting predicted but unexpectedly missing arguments of transitive verbs and searching the discourse for their referents. By hypothesis, this gap-driven search is what drives the identification of filler-gap dependencies between the ages of 15 and 20 months: As infants attempt to integrate more of the linguistic material in the sentence into a complete parse, they identify that a displaced argument stands in relation to that gap. Thus, it is consistent that gap detection precedes filler-gap dependency acquisition.

However, there are reasons to be skeptical of this account. First, as only two studies to date have examined *wh*-question comprehension in 15-month-olds and found contradictory results for *wh*-object questions, it remains to be seen which result will generalize. Second, Gagliardi, Mease & Lidz's data were noisy, and effects were found only in the second half of trials, making interpretation difficult. Finally, Gagliardi, Mease & Lidz's results provide only indirect evidence in support of their hypothesis. The ability to recognize filler-gap dependencies is only one of a range of developing abilities that could potentially cause a U-shaped learning trajectory on this task. Thus, more work is needed to both corroborate Gagliardi, Mease & Lidz's findings and provide additional evidence in support of their hypothesis.

2.3. This article

In this article, we aim to provide new evidence consistent with the gap-driven account of filler-gap dependency development. If 15-month-olds do not yet identify filler-gap dependencies in sentences that contain them but rather use a heuristic based on argument structure knowledge to infer what the experimenter is asking in these sentences, this makes the following prediction. Fifteen-month-olds will appear to comprehend subject and object *wh*-questions and relative clauses equally well, showing no subject-object asymmetry. But they will be able to do so only if they have learned enough verbs to reliably identify transitive clause structure and recognize when arguments are unexpectedly missing. We therefore expect vocabulary, as a proxy for verb knowledge, to predict children's performance at this age.

In the current study, we confirm this predicted effect of vocabulary on 15-month-olds' filler-gap dependency comprehension. In doing so, we partially reproduce Gagliardi, Mease & Lidz (2016) findings and bring new evidence to bear on the discrepancy over whether a subject-object asymmetry exists at this age: We provide another data point showing that 15-month-olds can perform equally well on subject versus object-gap *wh*-questions and relative clauses. Furthermore, by testing and confirming a prediction of the gap-driven hypothesis, we provide additional evidence consistent with that hypothesis. However, we acknowledge that this evidence is still highly indirect. Vocabulary size correlates with many developing capacities in infancy, which means that a vocabulary effect does not single out developing argument structure knowledge as the factor directly responsible for infants' success on our task. In our discussion, we examine several alternative accounts for these findings and discuss the steps needed for future work to identify more direct evidence for infants' filler-gap dependency representations at this age.

3. Method

We tested 15-month-olds' comprehension of *wh*-questions and relative clauses using a preferential looking task based on Gagliardi, Mease & Lidz (2016), modified to reduce memory demands. In the prior study, infants saw still images of event participants at test and needed to remember who did what to whom to respond to the test sentence. In our task, we presented looped videos of events during the test phase, so infants had access to participant role information while hearing the test sentences. Infants were tested in a 2×2 between-subjects design, crossing sentence type (*wh*-question vs. relative clause) and gap site (subject vs. object). Sample test sentences are provided in Table 1. To simplify our design, we tested only *that*-relative clauses, which 15-month-olds appeared to comprehend in prior work.

3.1. Participants

Participants included 64 typically developing infants (32 males) between the ages of 14;14 and 15;18 (mean: 14;29). Participants were recruited from the greater Washington, DC, area and were included in the final sample only if they heard English during at least 80% of their waking hours. We analyzed data from trials in which infants attended for at least 20% of the time during the test questions and only included infants who had at least four out of six usable trials. An additional 15 infants were tested but not included in the final sample due to fussiness or inattention (9), equipment malfunction (2), less than 80% English exposure (3), or a diagnosed developmental disorder (1).

Table 1. Sample test sentences (WH: *wh*-question, RC: relative clause).

	Subject	Object
WH	Which monkey is feeding the frog?	Which monkey is the frog feeding?
RC	Find the monkey that's feeding the frog.	Find the monkey that the frog is feeding.

Vocabulary was assessed by parental report using the Words and Sentences MacArthur-Bates Communicative Development Inventory (MCDI) (Fenson et al. 1993). Mean total productive vocabulary was 19.2 words (median: 12.5, range: 0–119). Mean productive verb vocabulary was 0.5 words (median: 0, range: 0–10). Because verb production was extremely low overall, we used total productive vocabulary as a proxy for verb knowledge in our analyses, under the assumption that the two are highly correlated and that production often lags behind comprehension in language development.

3.2. Materials

Videos of animal puppets (a frog and two different-colored monkeys) were filmed against a white background. Videos were digitally edited using Adobe Premiere video editing software to ensure consistent brightness and color contrast. Six events were filmed to depict the six familiar transitive verbs used in Gagliardi, Mease & Lidz (2016): *bump*, *hug*, *kiss*, *feed*, *tickle*, and *wash*. To facilitate counterbalancing of the participant roles of the monkey puppets, two pairs of videos were created for each event. In one pair, the frog acted on the brown monkey and the black monkey acted on the frog; in the second pair, the frog acted on the black monkey and the brown monkey acted on the frog. The timing of each video was edited to be consistent (6.8 seconds each), and events with shorter durations were looped and presented twice. Figure 1 shows sample still images from one pair of videos.

Audio stimuli were recorded by a female native speaker of American English using infant-directed speech. The audio was edited and combined with the video in Adobe Premiere. Table 2 shows the full set of audio stimuli during a trial. Where audio was the same across trials, the same recording was used to maintain consistency.

3.3. Procedure

Infants were seated on a parent’s lap or in a highchair in a dimly lit soundproof room, 6 feet away from a 51” widescreen plasma television. Parents were asked not to talk to their infants or direct their attention, and if they held their infant on their lap, they were asked to look away from the screen or wore a visor to prevent them from seeing the screen. A camera located above the television

Figure 1. Sample video stimuli, one pair of videos for “feeding” event.

Table 2. Structure of a trial. Asterisks mark audio that differs by condition.

Phase	Audio	Video
Familiarization	<i>Look, feeding! Somebody’s feeding somebody.</i> <i>Look, more feeding! Somebody’s feeding somebody.</i>	Frog feeds black monkey (6.8s) Brown monkey feeds frog (6.8s)
Salience	<i>Wow, look! They’re different!</i>	Both videos on loop (6.8s)
Test	<i>Which monkey is feeding the frog?*</i> <i>Which monkey is feeding the frog?*</i> Silence	Both videos on loop (6.8s) Blank screen (4s) Both videos on loop (6.8s)

was used to video-record each experiment at a capture rate of 29.97 frames per second. The camera's pan and zoom were controlled by an experimenter watching on a monitor in another room to ensure that infants' faces stayed within the frame throughout the experiment. Each experiment lasted 5.2 minutes.

The structure of the experiment is as follows. Infants were first introduced to the three animal puppets: the frog and the two monkeys. Each puppet appeared on the screen for 7 seconds with accompanying audio naming the animal (e.g., *Look, it's a brown monkey! Do you see the brown monkey?*). The two monkeys were differentiated by fur color (brown versus black) to ensure that infants perceived them as distinct.

After character introductions, each infant saw six trials consisting of a familiarization phase, a salience phase, and a test phase (Table 2). During the familiarization phase, infants saw a pair of videos for a particular event. In one video, the frog was the agent of the event and one of the monkeys was the patient; in the other video, the second monkey was the agent and the frog was the patient. The two videos were separated by a 0.5-second blank gray screen. The order of the two videos was counterbalanced across trials such that the first video showed the frog as the agent for half of the trials and a monkey as the agent for the other half of the trials. During each video, infants heard audio labeling the event in a transitive frame that did not specify the identity of either of the two participants (e.g., *Look, feeding! Somebody's feeding somebody*). This differed from the familiarization audio presented in Gagliardi, Mease & Lidz (2016), which named both participants in a way that varied by condition: In that study, a version of the test sentence for each condition was previewed during familiarization (e.g., *Which dog is gonna bump the cat?*), raising the possibility that infants were already differentially biased to look toward one of the two animals prior to the test phase. Our modified familiarization audio was intended to eliminate this confound by keeping the familiarization phase consistent across conditions.

The two familiarization videos were then played simultaneously on a loop in a smaller size on different sides of the screen. The actions moved toward the edge of the screen to draw infants' eyes away from the center. The left-right position of the target video for each condition was counterbalanced across trials. During the salience phase, infants heard uninformative audio (e.g., *Hey, look! They're different!*), allowing them to adjust to the split-screen format and examine both videos before the test phase began. The salience phase was also intended to reveal any baseline preferences for one of the two videos.

The test phase began after 6.8 seconds. The two looped videos continued to play as infants heard a test sentence that varied by condition (e.g., *Which monkey is feeding the frog?* or *Which monkey is the frog feeding?*). After another 6.8 seconds, the screen went blank, and infants heard a second repetition of the same test sentence to allow them to parse it without visual information. The videos reappeared after 4 seconds and played silently for another 6.8 seconds until the end of the trial. The decision to repeat the test sentence twice was motivated by the timing of the effects found in Gagliardi, Mease & Lidz (2016), which generally did not emerge until after the second presentation of the test sentence. It is plausible that infants needed a couple of opportunities to parse the sentence to demonstrate their comprehension in their task. However, as our task differs substantially from the prior study in both structure and timing (our test phase is much longer), we could not predict a priori that the time course of infants' behavior would be the same.

Within each condition, infants were assigned to one of two lists to counterbalance the participant roles of the two monkeys across events: In one list, videos for a particular event showed the black monkey as the agent and the brown monkey as the patient, and in the second list, these roles were reversed. Infants were also assigned to one of two random trial orders for each list. To focus infants' attention, trials were interleaved with either a 4-second still image of a baby face with audio of a baby giggling or a 14-second video of moving toys accompanied by music. Infants were given a break if they became restless or fussy.

4. Results

4.1. Data preparation

The videotaped recordings of the salience and test phases for each trial were coded off-line by an experimenter blind to the infant's experimental condition. Experimenters used Supercoder (Hollich 2005) to advance each muted video frame by frame and code whether infants were looking to the left or right of the screen or neither. Two coders coded these data, and intercoder reliability was established to be above 90% (Cohen's Kappa > 0.90).

4.2. Overall analysis

We first examined the general time course of looking patterns within the salience and test phase of a trial. At each frame, we calculated whether a participant was looking toward the video in which the monkey was the agent of the event, which was the target video for infants who heard subject-gap sentences (Subj) and the distractor video for infants who heard object-gap sentences (Obj). For each participant, we then averaged across all trials to compute the proportion of looks to the monkey-agent video at each frame, out of looks toward either video. Averaging across all participants for a condition provided a time course of the mean proportion of looks toward the monkey-agent video.

To determine whether looking patterns were conditioned on the linguistic stimuli, we selected three windows of analysis within the looking time course. The selected windows were the three seconds following the offset of each linguistic stimulus: the uninformative audio during the salience phase ("Salience Window"), the first repetition of the test sentence ("Test Window 1"), and the second repetition of the test sentence ("Test Window 2"). Note that these windows of analysis were longer than the 1.5-second windows chosen by Gagliardi, Mease & Lidz (2016), who were limited by the short length of their test phase; in our case, a longer test phase allowed us more time to examine infants' looking patterns.

Figure 2 displays the overall looking time course by sentence type. Looking times are divided into three panels: looking time during the salience phase on the left, during and following the first test sentence in the middle, and following the second test sentence on the right. We do not plot looking times during the second test question, as that question was presented over a blank screen. Instead, we plot looking times starting from the point when the videos reappeared on the screen until the end of the trial. At first glance, no systematic differences by condition are visually apparent during these time courses, with the exception of a fairly large backwards-looking pattern during the first test sentence in the *wh*-question condition: Infants appeared to be looking at the wrong answer even before the question began, and this persisted until roughly a second after the question finished.

The shaded gray regions represent the three selected windows of analysis, marking the three seconds after the offset of the uninformative salience audio or the first or second test sentences. Looking times during these windows were averaged for analysis. A 2×3 repeated-measures ANOVA (mean looks to monkey agent ~ gap site * window) was conducted for each sentence type (*wh*-questions and relative clauses), and found no main effects or interactions.³ Thus, when we average across all participants, we do not find a preference for the target video for any condition during these windows of analysis. This may be the result of (at least) two underlying causes. Either infants in general failed to identify the target video for their condition on our task, or some infants did actually succeed, but their responses were masked by another population of infants who did not. The latter possibility would be expected if infants' performance depended on their vocabulary, as predicted under our hypothesis.

³This particular analysis was chosen to be as similar as possible to the analysis conducted by Gagliardi, Mease & Lidz (2016), who used a very similar design. At the suggestion of an anonymous reviewer, we also examined the interaction by sentence type in each window separately. A 2×2 between-subjects ANOVA (mean looks to monkey agent ~ gap site * sentence type) conducted for each test window also did not find any significant main effects or interactions.

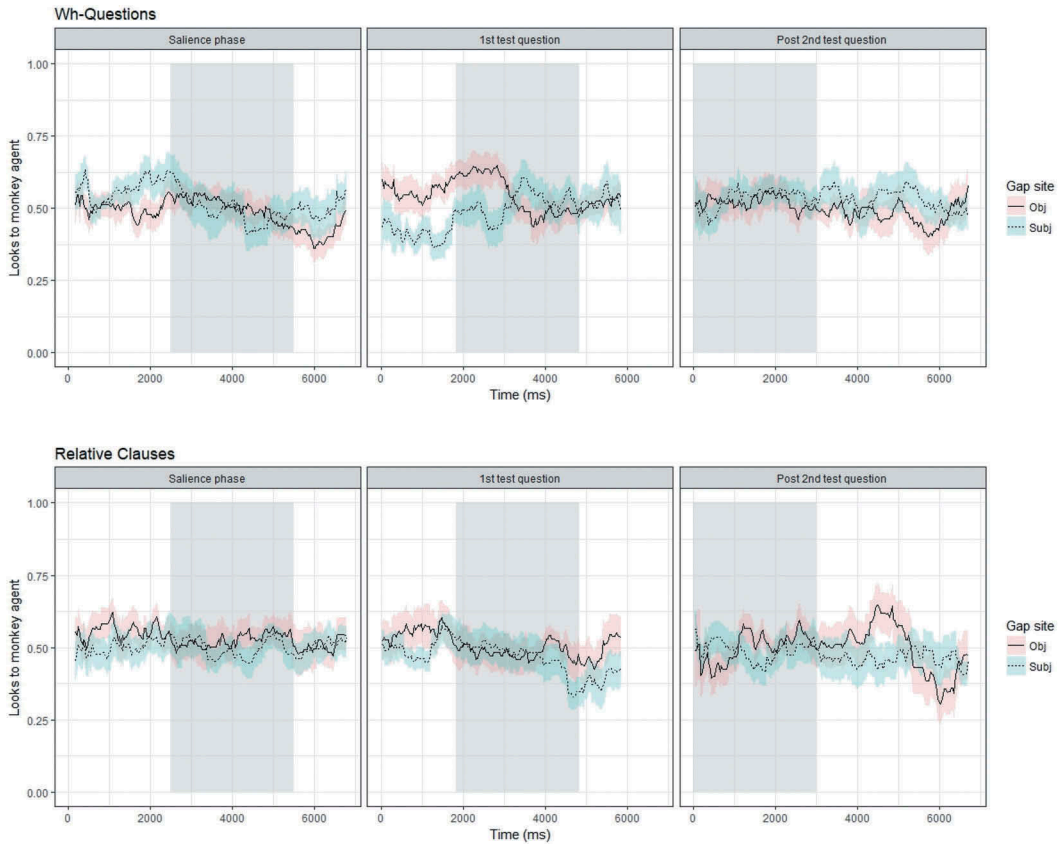

Figure 2. Time course of mean proportion looks to the monkey agent, all participants.

4.3. Vocabulary analysis

To test for the predicted vocabulary effect, we conducted a simple linear regression predicting looking time based on log-transformed total vocabulary as reported on the MCDI. Here, instead of using proportion looks to the monkey agent video as our dependent measure, we used proportion looks to the target video for each condition, out of looks to either the target or distractor. (Recall that the target video was the monkey agent video for subject-gap sentences and the monkey patient video for object-gap sentences.) We conducted a separate linear regression predicting the proportion looks to target in each of our three windows of analysis. In addition, to log vocabulary we included infants' age in days as a predictor in our regression model (looks to target \sim age in days + log vocab) to control for age effects.

For both *wh*-questions and relative clauses, a significant regression equation was found during Test Window 1, corresponding to 3 seconds following the first test question, WH: $F(2, 29) = 4.658$, $p < .018$, $R^2 = 0.243$; RC: $F(2, 29) = 4.053$, $p < .028$, $R^2 = 0.218$. Vocabulary was a significant predictor for both sentence types, WH: $t = 3.044$, $p < .005$; RC: $t = 2.815$, $p < .009$, but age in days was not. Figure 3 displays the relationship between looks to target and vocabulary in this first test window. No significant regression equation was found for the Salience Window or for Test Window 2.

To determine whether gap site (subject vs. object) also affected performance, in addition to vocabulary, we conducted a second simple linear regression in Test Window 1 in which we added gap site as a categorical variable (looks to target \sim age in days + log vocab + gap site). With this more complex model, a significant regression equation was found for *wh*-questions, and a marginally

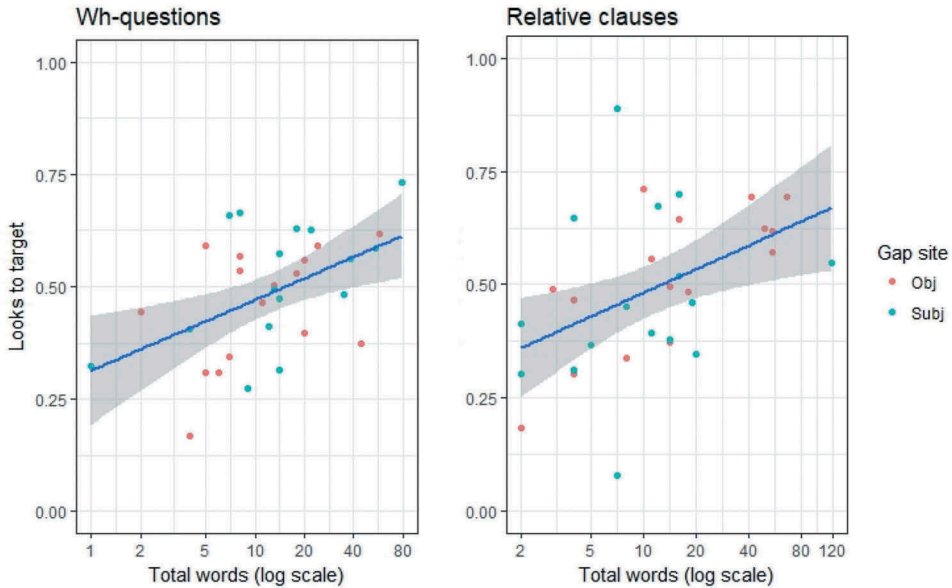

Figure 3. Relationship between vocabulary and looks to target during Test Window 1.

significant equation was found for relative clauses, WH: $F(3, 28) = 3.364$, $p < .032$, $R^2 = 0.265$; RC: $F(3, 28) = 2.676$, $p < .066$, $R^2 = 0.223$. Vocabulary remained a significant predictor for both sentence types, WH: $t = 2.889$, $p < .007$; RC: $t = 2.698$, $p < .011$, but gap site was not. We therefore find that only vocabulary predicts infants' performance on these sentence types; we do not find a difference in performance on subject versus object-gap sentences.

We visualized the vocabulary effect by conducting a median split on vocabulary and plotting the looking time course by both sentence type and vocabulary group. This time course is displayed in Figure 4, with gray bars still marking our windows of analysis. (Note that for ease of visualization we plot looks to the monkey agent rather than looks to target, but we continue to use looks to target as our dependent measure for analysis.) For both *wh*-questions and relative clauses, looking times for high-vocabulary infants appear to diverge in the expected direction during or shortly after the first test question. This is the window where vocabulary was found to be a significant predictor of performance. High-vocabulary infants who heard a subject-gap sentence appear to look more at the monkey agent, and high-vocabulary infants who heard an object-gap sentence appear to look more at the monkey patient; low-vocabulary infants do not show this same pattern.

However, these graphs also reveal that the time course of looking is slightly different for high-vocabulary infants who heard *wh*-questions and relative clauses. For *wh*-questions, conditions visually diverge in the expected direction roughly one second after the offset of the first test question, preceded by the same pattern of backwards looking that was observed in the overall data. For relative clauses, conditions visually diverge slightly before the offset of the first test sentence, until two seconds after sentence offset. We thus see an effect already in the first half of our window of analysis for relative clauses, but this effect doesn't emerge until the second half of our window for *wh*-questions. It is unclear why the time course of looking for these sentence types would differ, but this means that setting our windows of analysis a priori to the 3 seconds after sentence offset did not accurately capture infants' behavior in both conditions (see Delle Luche et al. 2015 for similar concerns about setting a fixed window of analysis before examining the looking time course of an experiment).

Figure 4. Time course of mean proportion looks to the monkey agent by vocabulary group.

To address this issue, we conducted a one-way repeated measures ANOVA comparing looks to target in the first and second halves of Test Window 1. For high-vocabulary infants, a significant effect of window half was found for relative clauses, $F(1, 14) = 11.29, p < .005$, and a marginally significant effect was found for *wh*-questions, $F(1, 16) = 4.20, p < .057$. No effects were found for low-vocabulary infants. Planned comparisons revealed that high-vocabulary infants looked at the target significantly above chance during the first half of Test Window 1 for relative clauses, $t(14) = 3.23, p < .006$, and during the second half of Test Window 1 for *wh*-questions, $t(16) = 2.21, p < .042$.

5. Discussion

These results show a predicted effect of vocabulary on 15-month-olds' comprehension of *wh*-questions and relative clauses. Although the time course of sentence processing appears to be different for the two types of sentences, high-vocabulary infants succeeded at identifying the target video during or shortly after the first test sentence for both sentence types. Low-vocabulary infants did not show this same pattern of success.

These results partially replicate the findings in Gagliardi, Mease & Lidz (2016): It appears that 15-month-olds can successfully identify the correct answer for both *wh*-questions and relative clauses and moreover can perform equally well on subject and object-gap sentences. However, there are some differences in our results compared to Gagliardi, Mease & Lidz's findings. We find that successful performance is modulated by vocabulary, whereas Gagliardi, Mease & Lidz found that successful performance was modulated by the time course of the experiment: Their effects only showed up during the second block of trials that infants saw. Furthermore, we find effects during the first presentation of the test sentence, whereas Gagliardi, Mease & Lidz found effects

during the second sentence presentation. These differences may be due to differences in the design of the current task. Our test phase is substantially longer than that in Gagliardi, Mease & Lidz, which may have given infants more time to process the stimuli earlier in the experiment. Presenting looped videos of the events at test, rather than still images of event participants, was also intended to reduce demands on memory and facilitate sentence processing. But processing the test sentence while viewing two simultaneously moving videos on the screen also introduces its own challenges, requiring infants to inhibit attention toward the movement in the distractor video to demonstrate a preference for the target video. Thus, further work is needed to determine the extent to which differences in results across the two studies may have been driven by task effects.

Despite these differences, our results are consistent with Gagliardi, Mease & Lidz's (2016) account of 15-month-olds' success on their task: namely, that 15-month-olds use argument structure knowledge to identify the right answer, without representing the filler-gap dependency in these sentences. Under this argument structure heuristic hypothesis, vocabulary is a proxy for more verb knowledge, resulting in an improved ability to identify transitive clause structure and notice predicted but missing arguments of transitive verbs. Infants may be able to infer that the experimenter is asking about that missing argument without realizing that the argument has been displaced via *wh*-movement to a higher clause position.

However, as vocabulary is correlated with many capacities in development, these results are also consistent with other accounts of infants' behavior. Perhaps the high-vocabulary 15-month-olds in our sample have actually acquired the syntax of *wh*-questions and relative clauses in English and are arriving at the correct answer in our task not through an interpretation heuristic but through adult-like representations of the filler-gap dependencies in these sentences. Under this first alternative account, vocabulary would be an index of broad syntactic development. On a second alternative account, perhaps all 15-month-olds have acquired the syntax of these sentence types, but only high-vocabulary infants can successfully deploy their knowledge to resolve the filler-gap dependencies in these sentences during online sentence processing. Here, vocabulary would be an index of faster or more automatic parsing abilities.

We find both of these alternatives somewhat less plausible given evidence that infants' syntactic abilities are still quite immature at this age. Infants prior to 20 months show variable abilities to recognize certain verbal and nominal morphology (Kouider et al. 2006; Santelmann & Jusczyk 1998) and map between a word's grammatical category and its meaning (Booth & Waxman 2009; He & Lidz 2017). Argument structure knowledge appears to be just emerging at this age and is apparent mostly for high-vocabulary infants (Lidz, White & Baier 2017) and in simplified task designs (Jin & Fisher 2014). An account based on developing argument structure may be easier to reconcile with the rest of the literature on infants' syntactic development than an alternative account based on adult-like representations of filler-gap dependencies. However, ruling out this alternative would require tasks that more directly probe infants' filler-gap dependency representations at this age, which we discuss in the following.

Even in the absence of definitive empirical evidence, we still believe there are some conceptual reasons to prefer the argument structure hypothesis over its alternatives. The first is parsimony: The argument structure hypothesis predicts a specific effect of vocabulary in our task and can also account for the independently observed relationship between vocabulary and emerging argument structure knowledge found in Lidz, White & Baier (2017). Under the alternative account on which higher-vocabulary infants have acquired the syntax of *wh*-questions and relative clauses, a vocabulary effect would also be predicted in our task. However, this hypothesis appears to miss a generalization: It does not appeal to the relationship between vocabulary and emerging argument structure knowledge evident around this same age and thus misses a potential link between the current results and those found in Lidz, White & Baier (2017).

Moreover, under the alternative account in which all infants have acquired *wh*-question and relative clause syntax, but higher-vocabulary infants have faster or more automatic parsing abilities,

a vocabulary effect is merely accommodated. If infants at all vocabulary levels have acquired the syntax of these sentence types, it could just as well have been the case that they would have no difficulty parsing the sentences in our task. Thus, the hypothesis that vocabulary indexes parsing ability can accommodate but does not explain the current results. Furthermore, if the high-vocabulary 15-month-olds succeeded at comprehending both *wh*-questions and relative clauses in our task due to superior parsing abilities, we lose an account of why 20-month-olds showed poorer performance on relative clauses compared to *wh*-questions in Gagliardi, Mease & Lidz (2016). Recall that the researchers explained these findings by appealing to mature knowledge of *wh*-dependencies at 20 months but difficulties deploying this knowledge online when processing relative clauses. This account received support from the observation that 20-month-olds improved when tested on *wh*-relatives compared to *that*-relatives. But if the high-vocabulary 15-month-olds in our sample are able not only to represent the filler-gap dependencies in *that*-relatives but also to parse them effectively online, presumably 20-month-olds would likewise have this ability. We thus lose an explanation for the prior finding that infants show different performance on relative clauses at these two ages.

Finally, if infants at any vocabulary level were representing the filler-gap dependency in these sentences, we might expect to see asymmetrical performance on subject-gap and object-gap sentences, which is a common signature of filler-gap dependency processing. A substantial literature on preschoolers' relative clause comprehension has found worse performance on object relatives than subject relatives (Adani et al. 2010; Arnon 2009; de Villiers et al. 1979; Friedmann, Belletti & Rizzi 2009; Goodluck & Tavakolian 1982; Hamburger & Crain 1982; Kidd & Bavin 2002; Labelle 1990; Sheldon 1974; Tavakolian 1981; among many others). Adults also display slower reading times for object compared to subject relatives during online sentence processing, which may be due to how memory is accessed when resolving dependencies over intervening linguistic material (see Wagers & Phillips 2014, for a review). If difficulty resolving longer dependencies for object relatives is responsible for the subject-object asymmetry, then we predict asymmetrical performance only if children are indeed attempting to resolve the dependency between the filler and the gap in these sentences.

For both *wh*-questions and relative clauses, the 15-month-olds we tested showed no evidence of asymmetrical performance with subject- versus object-gap sentences. Although it is difficult to reason about a null effect, the lack of a subject-object asymmetry is consistent with the hypothesis that infants do not yet represent the filler-gap dependencies in these sentences at this age. Furthermore, this result provides a further data point addressing the controversy in prior literature: We reproduce the lack of asymmetry found by Gagliardi, Mease & Lidz (2016), contra Seidl, Hollich & Jusczyk (2003). This lends support to Gagliardi, Mease & Lidz's interpretation of those earlier findings: The asymmetry found by Seidl, Hollich & Jusczyk may have arisen due to methodological factors and disappears when those factors are controlled.

These reasons aside, we acknowledge that the indirect nature of our evidence limits the conclusions we can draw about 15-month-olds' filler-gap dependency representations, and further empirical work is needed to provide more direct evidence. In ongoing work, we aim to distinguish whether 15- and 20-month-olds represent a fronted *wh*-phrase as an argument in a *wh*-question, or whether they merely notice when a verb is locally missing an argument. We use a listening time task (Maye, Werker & Gerken 2002; Shi, Werker & Cutler 2006) to test whether infants distinguish auditorily presented filled-gap *wh*-object questions (**Which dog should the cat bump him?*) from questions with gaps (*Which dog should the cat bump?*). We contrast these sentences with simple declaratives with and without direct objects (*The cat should bump him* and **The cat should bump*). To the greatest extent possible, we use the same familiar transitive verbs as in the current article. Sentences are presented in the absence of referential context: We no longer measure whether infants can identify an event that matches the sentence but merely whether infants listen longer to a grammatical or to an ungrammatical sentence.

Under our hypothesis, if 15-month-olds know the argument structure requirements of these transitive verbs and do not yet represent the *wh*-phrase as an object of the verb, they should process

a *wh*-question the same way they would process a simple transitive clause with no *wh*-phrase. In both cases, the absence of a direct object should be more surprising than an overt direct object. However, if older infants represent the *wh*-phrase as an argument, they should process a filled-gap question differently from a simple transitive clause: They should notice that the filled-gap question has too many arguments. We hope that further work of this sort will help address the limitations of the current study by probing more directly the nature of infants' argument structure knowledge and the structure of their *wh*-question representations at these two ages.

The results of the current study provide suggestive, although not conclusive, support for the hypothesis that infants rely on verb transitivity knowledge to identify filler-gap dependencies in sentences that contain them. But if this account is correct, we have a further puzzle: How can children learn verbs' distributional properties before they are able to identify instances of filler-gap dependencies, which obscure verb transitivity? That is, if children hear *wh*-object questions in such high frequency in their input but do not yet recognize the structure of those clauses as underlyingly transitive, what prevents them from drawing faulty inferences about the syntactic and semantic properties of verbs in those sentences? A common proposal in the literature is that children need to "filter out" filler-gap dependencies and other types of nonbasic clauses from the data they use for verb learning (Lidz & Gleitman 2004a, 2004b; Pinker 1984, 1989). In fact, it may be possible for learners to do so without identifying these clauses as nonbasic: Perkins, Feldman & Lidz (2017) found that a Bayesian computational model could simultaneously infer the transitivity of verbs in child-directed speech and the parameters for filtering noisy or misleading data out of its input, without knowing why those data were misleading. Thus, a child might first ignore filler-gap dependencies in her input to arrive at stable perceptions of verb transitivity and then to use verb transitivity to identify which sentences contain filler-gap dependencies.

Taken together with prior results, this work contributes to an incremental perspective on how children perceive and use the input to language acquisition. To identify the structure of sentences they hear, learners must rely on the immature linguistic knowledge they have acquired at their particular stage of development. We argue for a specific proposal implicating a tight relationship between verb argument structure and clause structure acquisition—namely, that argument structure knowledge acts as a catalyst for learners' identification of filler-gap dependencies in sentences that contain them. As the current findings provide suggestive but indirect evidence in favor of this proposal, this work invites further investigation into the nature and development of filler-gap dependency representations in infancy.
